

$$u^* = \sqrt{uv}$$

Pascal Michaillat, Emmanuel Saez

May 2024

This paper aims to compute the unemployment rate u^* that is consistent with full employment. First, it argues that the most appropriate economic translation of the legal notion of full employment is labor-market efficiency. Here efficiency requires to minimize the non-productive use of labor—both unemployment and recruiting. The nonproductive use of labor is measured by the number of jobseekers and vacancies, $u + v$. Through the Beveridge curve, the numbers of vacancies and jobseekers are inversely related, $uv = \text{constant}$. With such symmetry the labor market is efficient—at full employment—when there are as many jobseekers as vacancies ($u = v$), inefficiently tight when there are more vacancies than jobseekers ($v > u$), and inefficiently slack when there are more jobseekers than vacancies ($u > v$). Accordingly, the full-employment rate of unemployment (FERU) is the geometric average of the unemployment and vacancy rates: $u^* = \sqrt{uv}$. In the United States, 1930–2023, the FERU averages 4.1% and is much more stable than the actual unemployment rate. Therefore, the US labor market has generally been inefficiently slack, especially during recessions. The US labor market has only been inefficiently tight during major wars and the aftermath of the coronavirus pandemic.

1. Introduction

The US government's full-employment mandate. In the United States the federal government and central bank are mandated to maintain the economy at “full employment,” or “maximum employment”. This legislative mandate comes from the Employment Act of 1946, the Federal Reserve Reform Act of 1977, and the Full Employment and Balanced Growth Act of 1978 (Duboff 1977; Ginsburg 1979; Weir 1987; DeLong 1996; Steelman 2011; Bernanke 2013; Brainard 2021).¹ In this paper, we aim to compute the unemployment rate that characterizes a state of full or maximum employment. We denote it by u^* and, following Meade (1982), we refer to it as the full-employment unemployment rate (FERU).

Economic translation of the legal notion of full employment. First, we translate the legal notion of full employment into economic terms. Since the Employment Act and Full Employment and Balanced Growth Act clearly state that achieving full employment is a way to maximize social welfare, full employment should be translated to social efficiency. Indeed, the Employment Act states that reaching full employment is designed “to foster and promote ... the general welfare” (U.S. Congress 1946, p. 1). The Full Employment and Balanced Growth Act adds that when the economy departs from full employment, it “is deprived of the full supply of goods and services, the full utilization of labor and capital resources, and the related increases in economic well-being that would occur under conditions of genuine full employment, production” (U.S. Congress 1978, p. 1888). We therefore measure the FERU by the socially efficient rate of unemployment.

Existing full-employment target: NAIRU. The US government uses two unemployment rates as full-employment target. The first is the non-accelerating-inflation rate of unemployment (NAIRU), which is the unemployment rate at which inflation remains stable, and which is obtained by estimating Phillips curves (Staiger, Stock, and Watson 1997a,b; Gordon 1997; Laubach 2001; Ball and Mankiw 2002; Orphanides and Williams 2002; Crump et al. 2019). For instance, in a recent report, the U.S. Joint Economic Committee (2019, p. 2) notes that “Today, full employment is considered by many to be synonymous with the non-accelerating inflationary rate of unemployment (NAIRU)—the rate of unemployment that neither stokes nor slows inflation.” Similarly, the (U.S. Council of Economic Advisers 2024, p. 24) describes the concept of full employment as follows: “Modern economics has generally defined full employment by citing the theoretical concept of the lowest

¹In the legislative debate surrounding the Employment Act of 1946, “maximum” was seen as a less stringent goal than “full” (Duboff 1977, p. 6). In fact, the Employment Act of 1946 was a diluted version of the Full Employment Act of 1945, which was proposed but never passed in Congress. In 1978, the Employment Act of 1946 was amended by the Full Employment and Balanced Growth Act. One of the reasons behind the amendment was to bring back “full employment” into the text of law, instead of “maximum employment,” as full employment was considered to be a more ambitious target (Weir 1987, p. 398).

unemployment rate consistent with stable inflation, which is referred to as u^* , ... the non-accelerating inflationary rate of unemployment (termed NAIRU).” These quotes are particularly meaningful because they come from the Joint Economic Committee and Council of Economic Advisers, which were both created by the Employment Act of 1946 to ensure that the government achieved its employment mandate. But the NAIRU is not a measure of labor-market efficiency (Rogerson 1997, p. 90), so the NAIRU cannot be the FERU. The NAIRU might be helpful to achieve the Fed’s price-stability mandate, but it says nothing about the government’s full-employment mandate.

Existing full-employment target: CBO’s NRU. The second target used by the US government is the Congressional Budget Office (CBO)’s noncyclical rate of unemployment (NRU)—which was called “natural rate of unemployment” before 2021. The NRU is a slow-moving trend of the unemployment rate computed by aggregating slow-moving changes in the demographic composition of the labor force (Brauer 2007; Shackleton 2018; Bok et al. 2023). For example, when he was President of the Boston Fed, Rosengren (2014, p. 180) assessed how well the Fed adhered to its dual mandate, and in particular, he measured departure from the full-employment mandate by “the squared deviations of unemployment from an estimate of full employment utilizing the Congressional Budget Office (CBO) assessment of the natural rate for each year.” But trend unemployment is generally not efficient (Pissarides 2000, p. 185). Thus, the CBO’s NRU cannot be the FERU.

This paper’s full-employment target. We compute the FERU as the rate of unemployment that achieves an efficient allocation of labor. Such allocation maximizes social output by minimizing the uses of labor that are socially nonproductive: both unemployment and recruiting. The goal is that workers spend as much time as possible producing socially useful things and waste as little time as possible searching for jobs or new hires.

Social output. Social output is the amount of goods and services produced in the market and at home that enter social welfare. In theory, unemployed workers might produce valuable goods and services at home while looking for jobs. But in practice home production is minimal, so we assume that all production occurs in the market. Furthermore, not all workers employed in the market produce services that contribute to social welfare. Numerous workers devote their time to recruiting instead of producing goods and services that add to social welfare. In fact, it takes about one full-time worker to service any vacancy, so there are as many recruiters as vacancies. Hence, the objective is to minimize the sum of the unemployment and vacancy rates, $u + v$. Of course, jobseeking and recruiting are necessary for workers and firms to match with each other, but they do not generate any social welfare by themselves.

Beveridge curve. A naive way to minimize $u + v$ would be to set the unemployment rate u and vacancy rate v to zero. But it is impossible to reduce the numbers of jobseekers and vacancies at the same time because of the Beveridge curve. When the number of jobseekers falls along the Beveridge curve, the number of vacancies necessarily rises; conversely, when the number of vacancies falls, the number of jobseekers necessarily rises. In fact, the Beveridge curve is approximately a rectangular hyperbola: $uv = A$, where A is a constant. Hence, reducing either the unemployment or vacancy rate to zero pushes the other rate to infinity, which certainly does not minimize $u + v$.

Full-employment criterion. Because of the symmetrical roles played by jobseekers and vacancies, the economy is at full employment when there are as many jobseekers as vacancies ($u = v$). This is the only allocation that minimizes $u + v$ subject to $uv = A$. The labor market is inefficiently tight when there are more vacancies than jobseekers ($v > u$), and inefficiently slack when there are more jobseekers than vacancies ($u > v$). This full-employment criterion can be reformulated in terms of labor-market tightness, $\theta = v/u$. The labor-market tightness measures the number of vacancies per jobseeker. Our analysis implies that the full-employment tightness is $\theta^* = 1$. The labor market is inefficiently tight when $\theta > 1$ and inefficiently slack when $\theta < 1$.

Full-employment unemployment rate. Because the unemployment and vacancy rates play a symmetric role on the labor market, the FERU is the geometric average of the unemployment and vacancy rates: $u^* = \sqrt{uv}$. This formula arises by combining the Beveridge curve and the result that the efficient unemployment and vacancy rates are equal.

Deviations from full employment in the United States. Because it only requires unemployment and vacancy rates, the FERU formula $u^* = \sqrt{uv}$ is easy to apply. We compute the FERU between 1930 and 2023 in the United States. We find that the FERU is stable and averages 4.1%. Furthermore, we find that the FERU has generally been below the actual unemployment rate. That is, the US labor market has generally been inefficiently slack. The unemployment gap $u - u^*$ is especially wide in recessions—as wide as +20.9pp during the Great Depression and +5.9pp during the Great Recession. The US labor market has only been inefficiently tight during major wars—World War 2, Korean War, Vietnam War—and in the aftermath of the coronavirus pandemic.

Unusuality of the pandemic labor market. An advantage of the FERU formula is that it can be applied in real time. We can for example use it to examine the US labor market during the pandemic period, 2020–2023. We find that the pandemic labor market has been extremely unusual. First, in 2020, the unemployment gap reached +6.3pp. This is the

highest unemployment gap since World War 2; the last time the economy was so slack was in 1940, at the onset of World War 2. Then, in 2022, the unemployment gap bottomed to -1.4 pp. This is the lowest unemployment gap since World War 2; the last time the economy was so tight was in 1945, the end of World War 2. In fact, the number of vacancies has surpassed the number of jobseekers from 2021Q2 to the end of 2023, so the labor market has been inefficiently tight during this entire period. The pandemic is the only peacetime episode with such inefficient tightness in the United States.

2. Derivation of the FERU formula

This section derives the formula for the FERU: $u^* = \sqrt{uv}$.

2.1. The efficient allocation of labor

Based on the texts of law that introduced the full-employment mandate in the United States, we defined the FERU as the rate of unemployment that achieves an efficient allocation of labor. We describe this allocation here.

Maximizing social output. The efficient allocation of labor is the allocation that maximizes social output. Social output is the production of goods and services that generates social welfare. This perspective on full employment is consistent with the view expressed by Beveridge (1960, p. 20) that “The material end of all human activity is consumption. Employment is wanted as a means to more consumption . . . as a means to a higher standard of life.” Social output alone—not its distribution—determines social welfare because distributional considerations are excluded from the social welfare function.²

Connection with efficiency in matching models. The concept of efficiency used here is the same as in the modern labor-market models (Hosios 1990; Pissarides 2000). These models feature both unemployed workers and job vacancies, each inducing output losses: more unemployment means fewer people at work so less output; more vacancies means more labor devoted to recruiting and also less output. Distributional considerations are typically excluded from the social welfare function (Pissarides 2000, p. 184). Hence, the efficient allocation in these models maximizes output by minimizing the output loss caused by unemployment and recruiting.³

²Distributional considerations can be excluded by assuming that workers are risk neutral. If workers are risk averse and are not perfectly insured against unemployment, then the distribution of consumption matters for social welfare. In that case, the efficient unemployment rate is given by a more complex formula that incorporates distributional elements (Landais, Michailat, and Saez 2018a,b).

³The Hosios (1990) condition gives the bargaining power required for the market unemployment rate to be u^* under Nash bargaining. Instead, we determine the unemployment rate u^* that prevails when the labor market operates efficiently.

2.2. Workers available for market production

We first determine the pool of labor that is available for market production.

Full employment among labor-force participants. We assume that the social planner has the entire labor force at its disposal. This is a natural assumption. First, the laws that instated the full-employment mandate were designed to provide employment to labor-force participants. For instance, the Employment Act says that it aims to afford “useful employment opportunities, including self-employment, for those able, willing, and seeking to work” (U.S. Congress 1946, p. 1). The Full Employment and Balanced Growth Act uses similar language. Its goal is to “translate into practical reality the right of all Americans who are able, willing, and seeking to work to full opportunity for useful paid employment” (U.S. Congress 1978, p. 1887).

Taking the labor force as given. Given that anyone is free to enter the labor force, at no cost, if one desires, and that the social planner is not supposed to interfere with people’s free will, the social planner takes the labor force as given. The labor force represents the pool of workers that can be tapped for market production. People out of the labor force may be in school or training, may have retired, may be looking after their household or family, or may not be able to work. They are not available for market production.

Labor force over the business cycle. Although the social planner takes the labor force as given, the planner would have to account for changes in the labor force if the size of the labor force responded endogenously to the state of the labor market. In theory, two responses are possible: workers entering the labor force in bad times to supplement their household’s income, or jobseekers leaving the labor force in bad times out of discouragement. In practice, however, the labor-force participation rate appears acyclical, so variations in unemployment do not lead to systematic changes in participation. Using US data covering 1946–1954, Rees (1957, p. 32) did not find evidence of the discouraged-jobseeker theory. More systematically, Shimer (2009, p. 294) finds that labor-force participation is acyclical in US data covering 1960–2006. Similarly, using US data for 1976–2009, Rogerson and Shimer (2011, pp. 624–625) find that over the business cycle, “the labor force participation rate is nearly constant.” Erceg and Levin (2014, p. 19) also find that the labor-force participation rate is acyclical in the United States over 1972–2007.⁴ Finally, using a vector autoregression ran on quarterly US data covering the 1976–2016 period, Cairo, Fujita, and Morales-Jimenez (2022, figure 1C) find that the impulse response of the

⁴Erceg and Levin (2014) argue that high unemployment during the Great Recession caused a drop in US labor-force participation, but as Aaronson et al. (2014) and Krueger (2017) show, the decline in labor-force participation rate from 2007 was primarily caused by population aging and other trends that preceded the Great Recession.

labor-force participation rate to positive productivity shock (the stereotypical shock in business-cycle macro-labor models) is exactly zero at two years, and while it is slightly positive after two years, it is never significantly different from zero.

2.3. Social productivity of employed workers

The labor force is comprised of employed and unemployed workers. We start by assessing the social productivity of employed workers.

Breakdown of employed workers' time. We assume that all employed workers have the same productivity. However, workers are unable to spend their entire time contributing to social output. Instead they must spend some of their time recruiting new hires for their firms. Recruiting takes work: designing and posting vacancies, advertising, screening and interviewing candidates. This work that has to be diverted away from socially productive tasks. Beside recruiting, employed workers might also spend time looking for a new job, which takes further time away from production.

Labor required to service a vacancy. One source of information about the amount of labor devoted to recruiting in the United States is the National Employer Survey, which was conducted by the Census Bureau in 1997 (Villena Roldan 2010). The survey asked thousands of establishments across industries about their recruiting practices (Cappelli 2001). Using the survey, Michaillat and Saez (2021, p. 11) estimate that the amount of labor required to service a vacancy at any point in time is 0.92 worker. This number is close to that computed by Gavazza, Mongey, and Violante (2018) using data from a survey run by the consulting firm Bersin and Associates for 2011. The survey asked over 400 firms with more than 100 employees about their spending on all recruiting activities. Gavazza, Mongey, and Violante (2018, p. 2106) find that recruiting one worker cost 0.93 of a monthly wage. We also know that on average it takes a month to fill a vacancy in the United States (Landais, Michaillat, and Saez 2018b, online appendix B). Combining both results indicates that it takes on average 0.93 worker to service a vacancy.

Labor devoted to recruiting. Overall, both surveys show that it takes about 1 worker to service a vacancy. In other words, the number of recruiters in the United States is well measured by the number of vacancies.⁵ So the number of full-time workers diverted from producing and allocated to recruiting can be measured by the number of vacancies posted at any point in time.

⁵Section 4.2 shows how to extend the FERU formula if the number of recruiters required per vacancy is different from one.

Labor devoted to job-to-job search. Employed workers might also be distracted from producing if they search for new jobs at work. However, the average number of minutes spent on job search by employed workers is only 31 seconds per day (Ahn and Shao 2020, table 1). So it is a tiny amount taken away from production, and we abstract from it here.

2.4. Social productivity of unemployed workers

Next, we assess the social productivity of unemployed workers.

Breakdown of unemployed workers' time. We consider three possible activities for unemployed workers. One, of course, is looking for a job. Jobseeking is required to find employment but—just like recruiting—it does not contribute to social output. Second, unemployed workers might produce useful things at home. Such home production would add to social output and contribute to social welfare.

Value of home production versus psychological cost of idleness. The value of jobseekers' home production, net of the psychological cost of idleness, can be estimated from the results by Borgschulte and Martorell (2018). Using administrative data from the US military, Borgschulte and Martorell study how servicemembers choose between reenlisting and leaving the military. The choices allow them to estimate the value of home production plus public benefits minus the psychological cost of idleness during unemployment. Subtracting the value of public benefits from these estimates, Michaillat and Saez (2021, p. 11) find that the value of home production minus the psychological cost of idleness relative to the value of market production could be as low as 0.03. Given such low value, we set the value of home production minus the psychological cost of idleness to zero.⁶ That the social value of unemployment is essentially zero was already noted by Robinson (1949, p. 11): “The most important aspect of unemployment is its wastefulness. It is the existence of unused productive resources side by side with unsatisfied human needs that is the intolerable condition.”

Mechanisms behind the psychological cost of idleness. Where do the psychological costs of unemployment come from? The psychological costs associated with unemployment arise from various sources. First, depression, anxiety, and strained personal relations are common consequences of job loss (Eisenberg and Lazarfeld 1938; Theodossiou 1998). Job loss is a traumatic event that can lead to a decline in an individual's self-esteem and sense of self-worth (Goldsmith, Veum, and William Jr. 1996). Joblessness also diminishes psychological well-being by creating a sense of helplessness: that one's life is no longer under

⁶Section 4.2 shows how to extend the FERU formula if the value of home production, net of the psychological cost of idleness, is nonzero.

their control (Goldsmith and Darity 1992). Furthermore, job search appears to reduce unemployed workers' life satisfaction (Krueger and Mueller 2011). In fact, Jahoda (1981) emphasizes numerous important benefits of work—which are lost during unemployment. These benefits from work encompass a structured daily routine, regular interactions and shared experiences with individuals beyond the immediate family, the pursuit of overarching goals and purposes, a source of personal status and identity, and the engagement in regular activities. Collectively, the loss of these benefits contribute to the psychological burdens associated with unemployment.

Additional evidence on the psychological cost of idleness. The fact that the idleness associated with unemployment can create psychological hardship goes against the idea—standard in neoclassical economics—that unemployed workers enjoy leisure time. Yet, even though it is often neglected in economics, the psychological toll from unemployment has been understood for a long time. Robinson (1949, p. 11) for instance noted that “The most striking aspect of unemployment is the suffering of the unemployed and their families—the loss of health and morale that follows loss of income and occupation.” At this point, the detrimental effects of unemployment on mental and physical health are documented by a large literature (Dooley, Fielding, and Levi 1996; Murphy and Athanasou 1999; Platt and Hawton 2000; Frey and Stutzer 2002; McKee-Ryan et al. 2005; Winkelmann 2014). In a recent field experiment in Bangladesh, Hussam et al. (2022) find that unemployment has a large psychosocial cost. This cost manifests itself in two ways. First, paid employment raises psychosocial well-being substantially more than the same amount of cash alone. Second, two-thirds of employed workers would be willing to forgo cash payments and to continue working for free.

2.5. Shape of the Beveridge curve

Given that both unemployment and vacancies (measuring recruiting) are socially costly, the social planner would want to reduce both. This is not feasible, however, because of the Beveridge curve.

First observations of the Beveridge curve. Looking at labor-market statistics for Great Britain, Beveridge (1960) first noted that the number of vacancies and the number of jobseekers move in opposite directions. When the economy is in a slump, there are lots of jobseekers and few vacancies. Conversely, when the economy is in a boom, there are few jobseekers and many vacancies. This negative relationship between unemployment and vacancies—known as the Beveridge curve—was first plotted by Dow and Dicks-Mireaux (1958, figures 1 and 2) using data for Great Britain covering 1946–1956.

A. Regular scale

B. Log scale

FIGURE 1. Unemployment and vacancy rates in the United States, 1951–2019

The unemployment rate is measured by the U.S. Bureau of Labor Statistics (2024h). Between 1951 and 2000, the vacancy rate is constructed by Barnichon (2010); between 2001 and 2019, the vacancy rate is the number of job openings divided by the civilian labor force, both measured by the U.S. Bureau of Labor Statistics (2024a,c). Unemployment and vacancy rates are quarterly averages of monthly series. The gray areas are NBER-dated recessions.

Unemployment and vacancy rates move in opposite directions. The Beveridge curve holds remarkably well in the United States as well (Elsby, Michaels, and Ratner 2015). Figure 1A depicts the unemployment rate u (number of jobseekers divided by size of the labor force) and the vacancy rate v (number of vacancies divided by size of the labor force) in the United States from 1951 to 2019. The unemployment rate is measured by the U.S. Bureau of Labor Statistics (2024h). Between 1951 and 2000, the vacancy rate is constructed by Barnichon (2010). Between 2001 and 2019, the vacancy rate is the number of job openings divided by the civilian labor force, both measured by the U.S. Bureau of Labor Statistics (2024a,c). The figure shows that unemployment and vacancy rates move in opposite directions.

Unemployment and vacancy rates are inversely related. In fact, unemployment and vacancy appear to be the inverse of each other, so that doubling the unemployment rate cuts the vacancy rate in half, and conversely, doubling the vacancy rate cuts the unemployment rate in half. Figure 1B displays again unemployment and vacancy, but now in log scale. The fluctuations of the unemployment and vacancy rates are almost a mirror image of each other, indicating that unemployment and vacancy rates are inversely related. This empirical regularity was already noticed by Dow and Dicks-Mireaux (1958, p. 22) in Great Britain; it is striking because the two series are constructed independently of each other.

The Beveridge curve is a rectangular hyperbola. Mathematically, the property that the unemployment rate $u \in [0, 1]$ and vacancy rate $v \in [0, 1]$ are inversely related implies that the Beveridge curve is a rectangular hyperbola:

$$vu = A,$$

where $A \in (0, 1)$ is a constant.⁷

Estimates of the Beveridge elasticity. We can formally establish that the Beveridge curve is a rectangular hyperbola by estimating the elasticity of the vacancy rate with respect to the unemployment rate, $d \ln(v)/d \ln(u)$. An elasticity of -1 corresponds to an hyperbola. Using the algorithm of Bai and Perron (1998, 2003), and the data displayed in figure 1, Michaillat and Saez (2021, figures 5 and 6) estimate the structural breaks of the US Beveridge curve, and the elasticity of the Beveridge curve between these breaks. They find that over the 1951–2019 period, the Beveridge elasticity remains between -0.84 and -1.02 —never far from -1 . This finding confirms that the US Beveridge curve is close to a rectangular hyperbola.⁸

⁷Because each vacancy requires a recruiter, and there are fewer recruiters than labor-force participants, the vacancy rate (number of vacancies divided by size of the labor force) is at most 1: $v \in [0, 1]$. The constant A must be $(0, 1)$ so the equation $vu = A$ admits a solution (u, v) in $(0, 1) \times (0, 1)$.

⁸Section 4.2 shows how to extend the FERU formula if the Beveridge curve is an isoelastic curve with an elasticity different from 1.

Foundation for the hyperbolic Beveridge curve. It is quite natural that the empirical Beveridge curve is a rectangular hyperbola, since this is the shape that arises in the most basic matching model of the labor market. In matching models, the Beveridge curve is the locus of points such that labor-market flows are balanced: the number of workers who lose or quit their jobs equals the number of workers who find a job. The employment rate $1 - u$ is approximately constant around 1 since the unemployment rate u is an order of magnitude less than 1. The job-separation rate λ is also constant, so the number of job separations $\lambda(1 - u)$ is approximately constant around λ . So along the Beveridge curve, at any point of the business cycle, the number of workers who find a job is constant at λ . With the standard symmetric Cobb-Douglas matching function, $m = \omega \cdot \sqrt{uv}$, the number of workers who find a job at any point in time is proportional to \sqrt{uv} .⁹ Hence, along the Beveridge curve, \sqrt{uv} must be constant. In sum, $uv = \text{constant}$ along the Beveridge curve, so the Beveridge curve is a rectangular hyperbola.

Job-to-job transitions and labor-force transitions. We have just provided a foundation for the hyperbolic Beveridge curve based on the most basic matching model. But our analysis is in no way limited to such model: it only presumes that the Beveridge curve exists, but does not put additional restrictions on the structure of the labor market. For instance, the basic model only features flows between employment and unemployment. In practice, there are vast flows from employment to employment and in and out of the labor force (Abowd and Zellner 1985; Blanchard and Diamond 1990; Davis, Faberman, and Haltiwanger 2006). Our theoretical analysis of full employment applies in any model with such flows as long as they feature a Beveridge curve. Our analysis is in the sufficient-statistic tradition (Chetty 2009): the only structural element required for the analysis is the Beveridge curve. The Beveridge curve summarizes everything we need to know for the welfare analysis.¹⁰

Unemployment dynamics. The matching foundation for the Beveridge curve above also focuses on a state in which labor-market flows are balanced. But unemployment perpetually evolves through a dynamic process driven by differences between inflows into unemployment (job separations) and outflows from unemployment (job finding). The unemployment rate is on the Beveridge curve only when inflows and outflows are balanced. However, as (Pissarides 2009a, p. 236) notes, “Perhaps surprisingly at first, but on

⁹The US matching function appears to have a Cobb-Douglas form with exponents of 0.5 on unemployment and vacancies. See Michaillat and Saez (2021, p. 9) for a survey of US estimates based on aggregate data, and Petrongolo and Pissarides (2001) for a broader survey.

¹⁰Job-to-job transitions do not appear in our analysis because we assume that employed workers have the same social productivity in any firm, so the transitions do not affect welfare. Labor-force transitions do not appear in our analysis because we assume that all workers have the same social productivity. Since the size of the labor force is kept constant, a worker leaving the labor force must be replaced by a new worker entering the labor force (for instance a worker going on parental leave is replaced by a worker who has just finished parental leave). Such substitution has no effect on welfare.

reflection not so surprisingly, we get a good approximation to the dynamics of unemployment if we treat unemployment as if it were always on the Beveridge curve.” The reason is that in the United States, inflows and outflows are extremely large, so this dynamic unemployment process converges extremely quickly to the Beveridge curve. This explains why in matching models the labor market is always extremely close to the Beveridge curve—even if technically the Beveridge curve is a steady-state relationship—and why many matching models assume that the Beveridge curve holds at all times (Hall 2005; Pissarides 2009b; Elsby, Michaels, and Solon 2009). Formally, Michaillat and Saez (2021, p. 7) show that, given the job-finding and job-separation rates in the United States, about 50% of the deviation of the unemployment rate from the Beveridge curve evaporates within one month, and about 90% of it evaporates within one quarter, which implies that the unemployment rate is always in close proximity of the Beveridge curve.

2.6. Full-employment criterion

Given the social productivity of employed and unemployed workers and the shape of the Beveridge curve, we can formally describe the social planner’s problem.

Social objective. The social objective is to minimize the time spent on unemployment and recruiting at the expense of producing. We therefore define the socially efficient amount of unemployment as the amount that minimizes the nonproductive use of labor—both unemployment and recruiting. Since unemployment appears completely wasteful, and the amount of recruiting can be measured by the number of vacancies, the social objective is to minimize the sum of the unemployment and vacancy rates, $u + v$.

Optimization constraint. This minimization is subject to the Beveridge curve constraint, $uv = \text{constant}$. Because of the Beveridge curve, it is not possible to reduce unemployment and vacancies at the same time, and the social planner must trade off unemployment and vacancies. Given that the Beveridge curve is very stable over the business cycle, and does not seem to respond to stabilization policy—monetary or fiscal—in any systematic way, it makes sense that the social planner takes the Beveridge curve as given. In fact, in many business-cycle models with unemployment, the Beveridge curve is unaffected by monetary and fiscal policy (Cheron and Langot 2000; Walsh 2005; Faia 2008; Gertler, Sala, and Trigari 2008; Christoffel and Linzert 2010; Blanchard and Gali 2010; Ravenna and Walsh 2011; Michaillat 2014; Michaillat and Saez 2019, 2022, 2024).¹¹ In the context of business-cycle stabilization, it therefore seems appropriate to take the Beveridge curve as

¹¹In these models the Beveridge curve is determined by the matching function and job-separation rate. Neither responds to monetary or fiscal policy, so the Beveridge curve is unaffected by policy.

given.¹²

Solution by symmetry. The social planner thus minimizes $u + v$ subject to $uv = A$, with $u \in [0, 1]$ and $v \in [0, 1]$. Since the minimization problem is convex, it admits a unique minimum. And since this problem is perfectly symmetric in u and v , the minimum is reached when $u = v$.

Deviation from full employment. When the number of jobseekers is not equal to the number of vacancies, the labor market is operating inefficiently. The labor market is inefficiently tight when there are more vacancies than jobseekers ($v > u$). In that case, increasing u and reducing v would increase social output. The labor market is inefficiently slack when there are more jobseekers than vacancies ($u > v$). Then, reducing u and increasing v would increase social output.

First-order condition. We can also establish these results mathematically. The planner minimizes nonproduction $u + v$ subject to Beveridge curve $uv = A$, or $v = A/u$. This is equivalent to minimizing $u + A/u$ over, which is strictly convex in u , for $u \in (0, 1)$. A first-order condition is necessary and sufficient to find the minimum. We take the derivative of $u + A/u$ with respect to u and set it to 0. We obtain

$$1 - \frac{A}{u^2} = 0.$$

This condition implies that the minimum occurs when

$$u = \sqrt{A}.$$

By the Beveridge curve we have $v = A/u$, so at the minimum

$$v = \frac{A}{\sqrt{A}} = \sqrt{A}.$$

Accordingly, the full-employment unemployment and vacancy rates satisfy

$$u^* = v^* = \sqrt{A}.$$

Tightness formulation. The full-employment criterion can be reformulated in terms of labor-market tightness. The labor-market tightness is the ratio of vacancies to unemploy-

¹²While stabilization policies do not appear to affect the Beveridge curve, other policies do. For instance, a reduction in unemployment insurance bolsters the search effort of jobseekers, which shifts the Beveridge curve inward (Landaís, Michaillat, and Saez 2018b; Hochmuth et al. 2021). Structural policies designed to improve labor-market flows—such as the German Hartz reforms of 2003–2005—might also shift the Beveridge curve inward (Fahr and Sunde 2009; Klinger and Weber 2016).

ment, $\theta = v/u$. It measures the number of vacancies per unemployed workers. The analysis implies that the full-employment tightness is $\theta^* = 1$; that the labor market is inefficiently tight when $\theta > 1$; and that the labor market is inefficiently slack when $\theta < 1$.

2.7. FERU

Formula. We have seen that the FERU is given by $u^* = \sqrt{A}$ where the parameter A determines the location of Beveridge curve, $uv = A$. Hence, the FERU is the geometric average of the unemployment and vacancy rates:

$$u^* = \sqrt{uv}.$$

Intuitively, the FERU is the average of the unemployment and vacancy rates because unemployment and vacancy rates play a symmetric role on the labor market. Since $A > 0$, one basic implication of the formula $u^* = \sqrt{A}$ is that $u^* > 0$. In other words, the FERU is not zero: reaching full employment should not be interpreted as reaching zero unemployment.

The FERU is not zero, because zero unemployment is not feasible. The first, basic reason why the FERU is not zero is that because of the Beveridge curve, unemployment can never go to zero. Because each vacancy requires a recruiter, the vacancy rate v is at most 1. Accordingly, because of the Beveridge curve $u = A/v$, and $v < 1$, then $u > A$: the unemployment rate cannot fall below $A > 0$. The fact that labor-market flows impose a minimum level of unemployment—and therefore that full employment cannot be zero unemployment—has been known for a long time. Beveridge (1960, p. 125) realized that “However great the unsatisfied demand for labor, there is an irreducible minimum of unemployment, a margin in the labor force required to make change and movement possible.” As a result, “even under full employment, there will be some unemployment, ... on each day some men able and willing to work will not be working”. Similarly, Robinson (1946, pp. 169–170) noted that “In a changing world there are always bound to be, at any moment, some workers who have left one job and have not yet found another... Changes in occupation for personal reasons will always be going on. So long as such shifts in employment are taking place there is always likely to be some unemployment even when the general demand for labor is very high. Thus completely full employment can never be seen.”

The FERU is not zero, because zero unemployment is not desirable. Second, more interestingly, it is not efficient to reduce the unemployment rate to zero. Unemployment is clearly a waste of economic resources as people who would like to work and produce are not able to be productive. Yet, reducing the unemployment rate to zero is not desirable because, because of the Beveridge curve, it would require to divert a vast amount of labor toward

A. Visualization based on unemployment and vacancy rates

B. Visualization based on labor-market tightness

FIGURE 2. Deviation from full employment in the United States, 1951–2019

Unemployment and vacancy rates come from figure 1. Labor-market tightness is the ratio of the vacancy and unemployment rates. The gray areas are NBER-dated recessions. The labor market is at full employment when the unemployment rate equals the vacancy rate, is inefficiently slack when the unemployment rate is above the vacancy rate (purple shade), and is inefficiently tight when the unemployment rate is below the vacancy rate (orange shade). The US labor market is inefficiently tight during the Korean War (1951Q1–1953Q3) and Vietnam War (1965Q4–1970Q1), and at the end of the Trump presidency (2018Q2–2019Q4); it is inefficiently slack during the rest of the period 1951–2019.

A. Construction of the FERU

B. Distance from the FERU

FIGURE 3. FERU in the United States, 1951–2019

Unemployment rate u and vacancy rate v come from figure 1. The FERU is $u^* = \sqrt{uv}$. The gray areas are NBER-dated recessions.

recruiting. In fact, it is not efficient to reduce the unemployment rate below the vacancy rate. Reducing the unemployment rate by 1% requires to raise the vacancy rate by 1%, due to the Beveridge curve. When the unemployment rate is less than the vacancy rate, the increase in vacancy rate is more than the decrease in unemployment rate, so that overall, although the unemployment rate falls, the sum of the unemployment and vacancy rates increases. Accordingly, since $u \geq v$, $u^2 \geq uv = A$ and $u \geq \sqrt{A} > A > 0$. The fact that zero unemployment is not desirable arises here because of the resources diverted away from producing by vacancies and recruiting. Robinson (1946, p. 170) agreed that “no-one regards 100% employment as a desirable objective.” Her argument was that “the attainment of full employment, in this absolute sense, would require strict controls, including direction of labor” and that it would “involve great sacrifices of liberty”, even the “complete conscription of labor.”

3. Deviation from full employment in the United States

We compute the FERU in the United States in three periods: the standard postwar period, 1951–2019; the Great Depression and World War 2, 1930–1950; and the recent coronavirus pandemic, 2020–2023.

3.1. Postwar period

We first focus on the postwar period, 1951–2019. This is a standard period in the macro-labor literature, for which the unemployment and vacancy data are well known and well understood. For instance, Shimer (2005)’s seminal paper starts in 1951. We stop at the end of 2019 to avoid incorporating the pandemic, which is an extremely unusual period, and which we will discuss later (section 3.3).

Unemployment and vacancy rates. We use the standard, official measure of unemployment rate, constructed by the U.S. Bureau of Labor Statistics (2024h) from the Current Population Survey.¹³ We measure the vacancy rate from two different sources, because there is no continuous vacancy series over the period. For 1951–2000, we use the vacancy rate constructed by Barnichon (2010). This series is based on the help-wanted advertising index constructed by the Conference Board, corrected to account for the shift from print advertising to online advertising in the 1990s. The Conference Board index was compiled by aggregating help-wanted advertising in major metropolitan newspapers in the United

¹³The measure used here is labelled U3 by the U.S. Bureau of Labor Statistics (2023); it only includes jobseekers who want a job, are available to start a job now, and have been actively searching for a job in the past 4 weeks. Section 4.1 repeats the analysis with two broader measures of unemployment—U4 and U5—that include jobseekers with lower search effort. U4 and U5 add to U3 workers who want a job, are available to start a job now, have been actively searching for a job in the past 12 months but not in the past 4 weeks.

States. It has been showed to be a good proxy for job vacancies (Abraham 1987), and it has become standard in the macro-labor literature (Shimer 2005, p. 29). For 2001–2019, we use the number of job openings measured by the U.S. Bureau of Labor Statistics (2024c) in the Job Opening and Labor Turnover Survey, divided by the civilian labor force constructed by the U.S. Bureau of Labor Statistics (2024a) from the Current Population Survey. We then splice the two series to obtain a vacancy rate for 1951–2019. The unemployment and vacancy rates are plotted in figure 1.

Deviation from full employment. We assess the state of the US labor market between 1951 and 2019. We use the unemployment and vacancy rates from figure 1. The labor market is inefficiently slack whenever the unemployment rate is above the vacancy rate; it is inefficiently tight whenever the unemployment rate is below the vacancy rate. The unemployment rate averages 5.8% over the period, while the vacancy rate only averages 3.2%. So on average the unemployment rate is markedly higher than the vacancy rate, which shows that the US labor market is slack on average. In fact, between 1951 and 2019, the US labor market is always inefficiently slack except in three episodes (figure 2A): the Korean War (1951Q1–1953Q3), the Vietnam War (1965Q4–1970Q1), and the end of the Trump presidency (2018Q2–2019Q4).

Visualization with labor-market tightness. The state of the US labor market can also be visualized by plotting the labor-market tightness (figure 2B). The labor market is inefficiently slack whenever tightness is below 1, is inefficiently tight whenever tightness is above 1, and is at full employment when tightness equals 1—when there is just one vacancy per jobseeker. Tightness averages 0.62 between 1951 and 2019, well below 1, which is another manifestation that the US labor market is slack on average. Tightness peaked at 1.49 in 1953Q1, during the Korean War, and it bottomed at 0.16 in 2009Q3, during the Great Recession.

Full-employment unemployment rate. We then compute the FERU between 1951 and 2019 using the formula $u^* = \sqrt{uv}$. The FERU is fairly stable: it remains between 3.0% and 5.3%, with an average value of 4.2% (figure 3A).

Unemployment gap. We also compute the unemployment gap, which is the difference $u - u^*$ between the actual unemployment rate and the FERU. The unemployment gap indicates the distance from full employment at any given time. The unemployment gap is generally positive and sharply countercyclical (figure 3B). The unemployment gap averages 1.6pp over the 1951–2019 period. The unemployment gap peaked at +5.9pp in 2009Q4, during the Great Recession; the unemployment gap also reached the same value

in 1982Q4, at the end of the Volcker recession. In contrast, the lowest value taken by the unemployment gap is -0.6pp . The unemployment gap reached this value twice: in 1953Q1, during the Korean War; and in 1969Q1, during the Vietnam War. Hence, the economy is generally not at full employment, and it is especially far from full employment in recessions.

3.2. Great Depression and World War 2

Next, we apply our full-employment criterion and FERU formula to the historical period 1930–1950, which covers both the Great Depression and World War 2. Due to its simplicity, the FERU formula can easily be applied to historical data.

Unemployment and vacancy rates. The unemployment and vacancy rates for 1930–1950 are constructed by Petrosky-Nadeau and Zhang (2021). The vacancy rate is based on the Metropolitan Life Insurance Company help-wanted index, which was compiled by aggregating help-wanted advertising in newspapers across major US cities, and appears to be a good proxy for job vacancies (Zagorsky 1998). The unemployment rate is constructed from the annual unemployment series computed by Weir (1992), which is extended to a monthly series using unemployment rates compiled by the National Bureau of Economic Research (NBER) from various sources. Between 1930 and 1950 it remains true that unemployment and vacancy rates move in opposite directions (figure 4A).¹⁴

Hyperbolic Beveridge curve. Using a log scale, it also appears that unemployment and vacancy rates are inversely related (figure 4B). These fluctuations indicate that just as in the postwar era, the Beveridge curve is close to a rectangular hyperbola in 1930–1950. We also compute the elasticity of the 1930–1950 Beveridge curve by running an OLS regression of log vacancy rate on log unemployment rate. We find an elasticity of -0.79 , which is not far from the elasticity of -1 for a rectangular hyperbola, and is close to the elasticity of -0.84 for the 1951–1961 Beveridge curve (Michaillat and Saez 2021, figure 6). The 1930–1950 period saw vast fluctuations in unemployment and vacancy rates. The unemployment rate varied between 1.0% and 25.3%. The vacancy rate varied between 0.7% and 6.7%. Yet the hyperbolic shape of the Beveridge curve holds well over the entire range.

¹⁴Petrosky-Nadeau and Zhang (2021) produce a vacancy series that starts in 1919 and an unemployment series that starts in 1890. However, the vacancy numbers are unreliable for 1919–1923, because some important newspaper data are missing during that time (Zagorsky 1998, p. 339). Moreover, there is no monthly measure of unemployment between 1890 and 1929. Instead, between 1890 and 1918, the monthly unemployment fluctuations are inferred from the spread between the yields of high-grade and regular railroad bonds, and between 1919 and 1929, they are inferred from the spread between the yields of BAA-rated and AAA-rated corporate bonds. Given these limitations, we begin our analysis in 1930.

A. Regular scale

B. Log scale

FIGURE 4. Unemployment and vacancy rates in the United States, 1930–1950

The unemployment and vacancy rates are constructed by Petrosky-Nadeau and Zhang (2021). Unemployment and vacancy rates are quarterly averages of monthly series. The gray areas are NBER-dated recessions.

A. Visualization based on unemployment and vacancy rates

B. Visualization based on labor-market tightness

FIGURE 5. Deviation from full employment in the United States, 1930–1950

Unemployment and vacancy rates come from figure 4. Labor-market tightness is the ratio of the vacancy and unemployment rates. The gray areas are NBER-dated recessions. The labor market is at full employment when the unemployment rate equals the vacancy rate, is inefficiently slack when the unemployment rate is above the vacancy rate (purple shade), and is inefficiently tight when the unemployment rate is below the vacancy rate (orange shade). The US labor market is inefficiently tight during World War 2 (1942Q3–1946Q3); it is inefficiently slack during the rest of the period 1930–1950.

A. Construction of the FERU

B. Distance from the FERU

FIGURE 6. FERU in the United States, 1930–1950

Unemployment rate u and vacancy rate v come from figure 4. The FERU is $u^* = \sqrt{uv}$. The gray areas are NBER-dated recessions.

Deviation from full employment. The unemployment rate averages 9.0% over the period, while the vacancy rate only averages 2.3%. So on average the unemployment rate is markedly higher than the vacancy rate, which indicates that the US labor market is inefficiently slack on average. In fact, the US labor market is always inefficiently slack between 1930 and 1950 except at the end World War 2, during 1942Q3–1946Q3, when it was inefficiently tight (figure 5A).

Visualization with labor-market tightness. The state of the labor market can also be visualized by plotting labor-market tightness (figure 5B). Tightness averages $0.85 < 1$ between 1930 and 1950, which indicates that the US labor market is slack on average. Tightness is extremely volatile during the 1930–1950 period: it plunged to 0.03 in 1932Q3, during the Great Depression, and climbed all the way to 6.8 in 1944Q4, at the end of World War 2.

Full-employment unemployment rate. We then compute the FERU between 1930 and 1950 using the formula $u^* = \sqrt{uv}$. The FERU is again fairly stable: it remains between 2.5% and 4.6%, with an average value of 3.5% (figure 6A).

Unemployment gap. Finally, we compute the unemployment gap, which is the difference $u - u^*$ between the actual unemployment rate and the FERU (figure 6B). The unemployment gap averages 5.5pp between 1930 and 1950. The unemployment gap was of course positive and very large during the Great Depression: the labor market was much too slack then. The unemployment gap reached +20.9pp in 1932Q3. The economy recovered only slowly from the Great Depression. The economy only reached full employment in 1942Q3, a few quarters after the United States had entered World War 2. The unemployment gap kept falling during the war; it reached –1.6pp in 1945Q1. The unemployment gap turned positive again during the 1948–1949 recession.

3.3. Coronavirus pandemic

Finally, we apply our full-employment criterion and FERU formula to the coronavirus pandemic in the United States. We focus on the three-year period between January 2020 and December 2023. Here, the simplicity of our FERU formula allows us to apply to real-time data and assess the current state of the labor market.

Unemployment and vacancy rates. The unemployment rate is measured by the U.S. Bureau of Labor Statistics (2024h). The vacancy rate is the number of job openings divided by the civilian labor force, both measured by the U.S. Bureau of Labor Statistics (2024a,c). Both series are displayed on figure 7A. The unemployment rate averages 5.2% over 2020–2023. The vacancy rate averages 5.6% over the same period.

A. Visualization based on unemployment and vacancy rates

B. Visualization based on labor-market tightness

FIGURE 7. Deviation from full employment in the United States, 2020–2023

The unemployment rate is measured by the U.S. Bureau of Labor Statistics (2024h). The vacancy rate is the number of job openings divided by the civilian labor force, both measured by the U.S. Bureau of Labor Statistics (2024a,c). Unemployment and vacancy rates are quarterly averages of monthly series. The labor-market tightness is the ratio of the vacancy and unemployment rates. The gray area is the NBER-dated pandemic recession. The labor market is at full employment when the unemployment rate equals the vacancy rate, is inefficiently slack when the unemployment rate is above the vacancy rate (purple shade), and is inefficiently tight when the unemployment rate is below the vacancy rate (orange shade). The US labor market is inefficiently tight in 2021Q3–2023Q4 and inefficiently slack in 2020Q2–2021Q2.

A. Construction of the FERU

B. Distance from the FERU

FIGURE 8. FERU in the United States, 2020–2023

Unemployment rate u and vacancy rate v come from figure 7A. The FERU is $u^* = \sqrt{uv}$. The gray area is the NBER-dated pandemic recession.

Deviation from full employment. The labor market is inefficiently slack whenever the unemployment rate is above the vacancy rate; it is inefficiently tight whenever the unemployment rate is below the vacancy rate. We find that the US labor market is inefficiently slack from 2020Q2 to 2021Q2; it is inefficiently tight from 2021Q3 to 2023Q4 (figure 7A).

Visualization with labor-market tightness. The state of the US labor market can also be visualized by plotting labor-market tightness (figure 7B). The labor market is inefficiently slack whenever tightness is below 1; it is inefficiently tight whenever tightness is above 1. Tightness averages 1.31 over the 2020–2023 period. Tightness cratered to 0.26 in 2020Q2, so the labor market was much too slack at the beginning of the pandemic. It then steadily recovered to reach 1.97 in 2022Q2. At that point, the labor market was much too tight. The labor market passed the point of full employment (tightness of 1) in the middle of 2021. After peaking in 2022Q2, tightness slowly fell to reach 1.44 at the end of 2023. So the labor market remains inefficiently tight at the end of 2023, but it is approaching full employment.

Full-employment unemployment rate. We then compute the FERU between 2020 and 2023 using the formula $u^* = \sqrt{uv}$. The FERU averages 5.1% over the period. The FERU was 4.0% in 2020Q1, at the onset of the pandemic, but it sharply increased to 6.6% in the next quarter (figure 8A). It hovered around 6.0% during the rest of the 2020–2021 period, and slowly decreased to 4.5% at the end of 2023.

Unemployment gap. We also compute the unemployment gap, which is the difference $u - u^*$ between the actual unemployment rate and the FERU (figure 8B). While the unemployment gap averages 0 over the period, the labor market experienced sharp departures from full employment. The unemployment gap was initially positive and large: the labor market was much too slack in the first year of the pandemic. The unemployment gap reached +6.4pp in 2020Q2. But the economy recovered quickly and reached full employment in the middle of 2021. The unemployment gap turned negative after that, reaching –1.4pp in 2022Q2. The unemployment gap then shrunk to –0.7pp in 2023Q4. So in 2022–2023, the labor market was well beyond full employment.

The sudden rise of the FERU. The FERU increased by more than 2pp at the onset of the pandemic. Such a sharp increase is unprecedented. It can be explained by the gigantic outward shift of the Beveridge curve that took place in the spring 2020. Graphically, the FERU appears at the intersection of the Beveridge curve and the pink identity line (figure 9). In 2020Q1, at the onset of the pandemic, the labor market was close to full employment, and the unemployment rate was at 3.8%. In 2021Q2, about a year later, the labor market

FIGURE 9. Beveridge curve in the United States, 2001–2023

Each dot represents the unemployment and vacancy rates in a quarter between 2001 and 2023. The unemployment rate is measured by the U.S. Bureau of Labor Statistics (2024h). The vacancy rate is the number of job openings divided by the civilian labor force, both measured by the U.S. Bureau of Labor Statistics (2024a,c). The labor market is at full employment when the unemployment rate equals the vacancy rate (pink line); it is inefficiently slack when the vacancy rate is below the unemployment rate (purple dots); it is inefficiently tight when the vacancy rate is above the unemployment rate (orange dots).

had returned to the vicinity of full employment, but the unemployment rate was now 5.9%. Indeed, the FERU rose from 4.0% to 5.8% from 2020Q1 to 2021Q2. This rise was caused by the outward shift of the Beveridge curve that occurred between the first and second quarters of 2020. Mathematically, the FERU is determined by the location of the Beveridge curve ($u^* = \sqrt{A}$), so only a sharp outward shift of the Beveridge curve (increase in A) can increase the FERU.¹⁵

3.4. Complete 1930–2023 period

To conclude, we combine the US unemployment and vacancy rates from 1930 to 2023.

Deviation from full employment. Between 1930 and 2023, the unemployment rate averages 6.5%. The vacancy rate averages slightly less than half of that, 3.1%. The unemployment rate is generally above the vacancy rate, and this gap is exacerbated in recessions (figure 10A). This means that the labor market does not generally operate at full employment;

¹⁵The previous shifts of the Beveridge curve during the postwar period were not large enough to produce noteworthy changes in the FERU (figure ??).

A. Visualization based on unemployment and vacancy rates

B. Visualization based on labor-market tightness

FIGURE 10. Deviation from full employment in the United States, 1930–2023

Unemployment and vacancy rates are obtained by splicing the unemployment and vacancy rates from figures 1, 4, and 7A. Labor-market tightness is the ratio of the vacancy and unemployment rates. The gray areas are NBER-dated recessions. The labor market is at full employment when the unemployment rate equals the vacancy rate, is inefficiently slack when the unemployment rate is above the vacancy rate (purple shade), and is inefficiently tight when the unemployment rate is below the vacancy rate (orange shade). The figure summarizes the findings from figures 2, 5, and 7.

instead, it is generally inefficiently slack. Before 2018, the labor market is only inefficiently tight during major wars—World War 2, Korean War, Vietnam War. Since then the labor market has been inefficiently tight at the end of the Trump presidency and during the recovery of the coronavirus pandemic. The state of the labor market around the pandemic, in 2018–2019 and 2021–2023, is a rarity. It is the only peacetime labor market that is exceedingly tight. Keynes (1936, p. 322) doubted that the labor market could reach full employment in peacetime. He was essentially right: before 2018 the US labor market had never reached full employment in peacetime.

Visualization with labor-market tightness. The state of the labor market can also be visualized by plotting labor-market tightness (figure 10B). Over 1930–2023, labor-market tightness averages 0.69. Tightness is extremely volatile before the end of World War 2. Tightness records its most extreme fluctuations during that period: tightness plunged to 0.03 in 1932Q3, during the Great Depression, and climbed all the way to 6.8 in 1944Q4, at the end of World War 2. In 2022, tightness reached a value of 1.97, which it had last reached in 1945. In the recovery of the pandemic, the US labor market has become historically tight.

FERU. Over 1930–2023, the FERU averages 4.1% (figure 11A). The FERU is stable over time, remaining between 2.5% and 6.6% over almost a century. It hovered around 4% between 1930 and 1970. It rose to about 5% in the 1970s and stayed there in the 1980s. It then remained around 4% again between 1990 and 2020. Finally, it temporarily rose to 6% during the pandemic. Overall, in the United States, the FERU is stable over time, generally around 4%.

Unemployment gap. Finally, over 1930–2023, the unemployment gap averages 4.1% (figure 11A). The unemployment gap reached +20.9pp in 1932Q3—its highest level on record—during the Great Depression. The unemployment gap reached –1.6pp in 1945Q1—its lowest level on record—at the end of World War 2. Another notable peak for the unemployment gap is +6.3pp in 2020Q2—its highest level in the postwar period, in the middle of the coronavirus pandemic. In the aftermath of the pandemic the unemployment gap fell to –1.4pp in 2022Q2. This is the lowest unemployment gap in the postwar period.

4. Robustness

This section shows that the results are robust to different measurements of the labor force and unemployment, and to different calibrations of the cost of unemployment, cost of recruiting, and shape of the Beveridge curve.

A. Value of the FERU

B. Distance from the FERU

FIGURE 11. FERU in the United States, 1930–2023

The FERU is obtained by splicing the FERUs from figures 3A, 6A, and 8A. The unemployment rate is obtained by splicing the unemployment rates from figures 1, 4, and 7A. The gray areas are NBER-dated recessions.

A. Alternative FERUs

B. Alternative unemployment gaps

FIGURE 12. Alternative measures of full employment in the United States, 1994–2023

The FERUs are given by $u3^* = \sqrt{u3 \times v3}$, $u4^* = \sqrt{u4 \times v4}$, and $u5^* = \sqrt{u5 \times v5}$. The unemployment rate $u3$ is measured by the U.S. Bureau of Labor Statistics (2024h); the unemployment rate $u4$ is measured by the U.S. Bureau of Labor Statistics (2024f); the unemployment rate $u5$ is measured by the U.S. Bureau of Labor Statistics (2024g). The vacancy level comes from figure 10A. The vacancy rate $v3$ is the vacancy level divided by the number of labor-force participants, which is measured by the U.S. Bureau of Labor Statistics (2024a). The vacancy rate $v4$ is the vacancy level divided by the number of labor-force participants and discouraged workers, both measured by the U.S. Bureau of Labor Statistics (2024a,d). The vacancy rate $v5$ is the vacancy level divided by the number of labor-force participants and marginally attached workers, both measured by the U.S. Bureau of Labor Statistics (2024a,e). Unemployment and vacancy rates are quarterly averages of monthly series. The gray areas are NBER-dated recessions.

4.1. Alternative measures of the labor force and unemployment

Standard definitions of the labor force and unemployment. By definition, the labor force comprises people able, willing, and seeking to work. This definition seems quite natural. Anyone willing to work would also be seeking to work, otherwise they could never get a job; seeking a job reveals willingness to work. One empirical challenge, however, is to determine who is searching for a job. People search with different intensity and methods. Ideally anyone searching in anyway would be counted in the labor force. However, the standard US statistics only include unemployed people who have been actively searching in the past 4 weeks into the labor force. There is a group of workers—amounting to about 1% of the labor force—who have been searching for a job in the past year but not in the past month who are excluded from the labor force statistics, although in theory they belong there. When we apply the FERU formula to the US economy in section 3, we stick to the official definition of the labor force and unemployment. Here we recompute the FERU using broader definitions of the labor force and unemployment—replacing the unemployment rate $U3$ by the broader unemployment rates $U4$ and $U5$, and adjusting the size of the labor force accordingly. To clarify that our baseline measures of unemployment and the labor force are based on the concept $U3$ of unemployment, in this section we denote these unemployment and vacancy rates as $u3$ and $v3$ instead of u and v .

Broader definitions of unemployment: $U4$. The unemployment concept $U4$ includes all the workers in the standard unemployment concept $U3$, plus workers who want a job, are available to start a job now, have been actively searching for a job in the past 12 months, but have not been searching in the past 4 weeks because they became discouraged about their job prospects (U.S. Bureau of Labor Statistics 2023). When asked why they did not look for work during the last 4 weeks, these workers respond for instance that “There are no jobs available”, or “They have been unable to find work in the past.” These additional workers are labelled “discouraged workers.” They are not classified as part of $U3$ because they did not actively search for work in the last 4 weeks.

Broader definitions of unemployment: $U5$. The unemployment concept $U5$ includes all the workers in $U4$ plus workers who want a job, are available to start a job now, have been actively searching for a job in the past 12 months, but have not been searching in the past 4 weeks for other reasons than discouragement about their job prospects (U.S. Bureau of Labor Statistics 2023). When asked why they did not look for work during the last 4 weeks, these workers respond for instance that they could not search because of family responsibilities, childcare problems, or ill health. These additional workers are not classified in $U3$ because they did not actively search for work in the last 4 weeks; they are not classified in $U4$ because they were not discouraged about their job prospects. Together

with the discouraged workers, these workers compose the “marginally attached workers.”

Broader definitions of the labor force. To be consistent with the definitions U4 and U5 of the unemployment level, the definition of the labor force is also adjusted approximately. These broader labor-force sizes are used to compute unemployment and vacancy rates.

Broader unemployment and vacancy rates. The unemployment rate $u4$ is the unemployment level U4 divided by an extended labor force, composed of the standard labor force plus the discouraged workers. This unemployment rate is constructed by the U.S. Bureau of Labor Statistics (2024f). We also compute a vacancy rate $v4$ by taking the vacancy level constructed in section 3.4 and dividing it by the number of workers in the standard labor force plus the number of discouraged workers, both constructed by the U.S. Bureau of Labor Statistics (2024a,d). In that way, the rates $u4$ and $v4$ have the same denominator. Similarly, the unemployment rate $u5$ is the unemployment level U5 divided by an extended labor force, composed of the standard labor force plus the marginally attached workers. This unemployment rate is constructed by the U.S. Bureau of Labor Statistics (2024g). We compute a vacancy rate $v5$ by taking the vacancy level constructed in section 3.4 and dividing it by the standard labor force plus the marginally attached workers, both constructed by the U.S. Bureau of Labor Statistics (2024a,e). The unemployment levels U4 and U5 were only introduced in 1994, so we can only measure $u4$, $v4$, $u5$, $v5$ during that period. For reference, the average value of the standard unemployment rate, $u3$, over the 1994–2023 period is 5.6%. By comparison, the average value of $u4$ is 6.0%, and the average value of $u5$ is 6.7%. So the discouraged workers make up less than half a percentage point of the labor force, and the marginally attached workers make up about one percentage point of the labor force. By construction, all the vacancy rates are quite close, averaging 3.3% over the period.

Broader definitions of the FERU. Using these broader measures of unemployment and the labor force, we construct broader measures of the FERU: $u4^* = \sqrt{u4 \times v4}$, and $u5^* = \sqrt{u5 \times v5}$ (figure 12A). We compare these measures to the standard value of the FERU: $u3^* = \sqrt{u3 \times v3}$. Over the 1994–2023 period, the average value of $u3^*$ is 4.2%, the average value of $u4^*$ is 4.3%, and the average value of $u5^*$ is 4.5%. So the three measures of the FERU are very close to each other—much closer in fact than the three measures of unemployment. The average distance between $u3$ and $u4$ is 0.4pp while the average distance between $u3^*$ and $u4^*$ is only 0.1pp; the average distance between $u3$ and $u5$ is 1.1pp while the average distance between $u3^*$ and $u5^*$ is only 0.3pp. We also see that all measures of the FERU follow the exact same patterns: the largest distance between $u3^*$ and $u4^*$ is only 0.2pp and the largest distance between $u3^*$ and $u5^*$ is only 0.6pp. The final readings of the FERU in

2023Q4 are $u3^* = 4.5\%$, $u4^* = 4.6\%$, $u5^* = 5.0\%$.

Broader definitions of the unemployment gap. Using these broader measures of unemployment and the labor force, we also construct broader measures of the unemployment gap: $u4 - u4^*$ and $u5 - u5^*$ (figure 12B). The different measures of unemployment gap all move together. The unemployment gaps constructed with the broader measures of unemployment are larger than the baseline unemployment gap, because the unemployment rates $u4$ and $u5$ are larger than $u3$, but the differences are not as large as the differences in unemployment rates because part of it is absorbed by the differences in FERUs. Over the 1994–2023 period, the gap $u3 - u3^*$ averages 1.5pp, the gap $u4 - u4^*$ averages 1.7pp, and the gap $u5 - u5^*$ averages 2.2pp. Because the unemployment gap is larger with the broader measures of unemployment, the economy appears exactly at full employment—and not inefficiently tight—in 2019 under U5. The final readings of the unemployment gap in 2023Q4 are $u3 - u3^* = -0.7\text{pp}$, $u4 - u4^* = -0.6\text{pp}$, and $u5 - u5^* = -0.4\text{pp}$. So all unemployment gaps are negative, which indicates that the labor market is inefficiently tight for all measures of unemployment at the end of 2023.

4.2. Alternative calibrations of the cost of unemployment, cost of recruiting, and shape of the Beveridge curve

Generalized FERU formula. We derive the formula $u^* = \sqrt{uv}$ by assuming that jobseekers do not contribute to social welfare, that a 1% increase in unemployment affords a 1% decrease in vacancies (Beveridge elasticity of 1), and that one vacancy requires one recruiter. These assumptions are based on evidence for the United States. It is possible to generalize the formula for the FERU under a more general calibration. If the Beveridge elasticity is $\epsilon \neq 1$, the social value of nonwork is $\zeta > 0$, and the recruiting cost is $\kappa \neq 1$, then the FERU becomes

$$(1) \quad u^* = \left(\frac{\kappa\epsilon}{1-\zeta} \cdot \frac{v}{u^{-\epsilon}} \right)^{1/(1+\epsilon)},$$

as showed by Michaillat and Saez (2021, proposition 3). Note that by setting $\epsilon = 1$, $\kappa = 1$, and $\zeta = 0$ in formula (1), we recover the simpler formula $u^* = \sqrt{uv}$.

Distance between basic and generalized FERU. The generalized formula requires to keep track of three statistics in addition to the unemployment and vacancy rates (ϵ , ζ , κ), so it is harder for policymakers to compute than the simple $u^* = \sqrt{uv}$. The generalized formula is especially difficult to apply in real time because it requires to keep track of the slope of the Beveridge curve, and that is hard to do when the Beveridge curve shifts. By setting the sufficient statistics to reasonable but fixed values, we obtain a formula that is simple

FIGURE 13. FERU under alternative calibration of the social costs and benefits of unemployment

The solid, pink line reproduces the FERU from figure 3A. The dotted, purple line is the FERU under the Beveridge elasticity ϵ estimated by Michaillat and Saez (2021, figure 6), the social value of nonwork $\zeta = 0.26$, and the recruiting cost $\kappa = 0.92$, as constructed by Michaillat and Saez (2021, figure 7B). The gray areas are NBER-dated recessions.

and user-friendly, and therefore appropriate to measure full employment in real time. In the United States, however, the two formulas yield almost identical unemployment rates (figure 13). The generalized FERU formula is applied using under the Beveridge elasticity ϵ estimated by Michaillat and Saez (2021, figure 6), the social value of nonwork $\zeta = 0.26$, and the recruiting cost $\kappa = 0.92$, as constructed by Michaillat and Saez (2021, figure 7B). Over 1951–2019, the two FERUs depart by only 0.2pp on average, and they never depart by more than 0.5pp.¹⁶

5. Theoretical underpinning of various criteria for full employment

Policymakers in charge of stabilization in the United States measure full employment by the NAIRU or the CBO's NRU. However, other people have proposed criteria for full employment that resemble our criterion. In this section, we examine how our analysis provides a theoretical underpinning for these older ideas.

¹⁶In other contexts—other countries, local labor markets, sectoral labor markets—it might be necessary to use the more general formula and adjust the calibration of the statistics to obtain an accurate measure of the FERU.

5.1. Beveridge's criterion

Beveridge (1960, p. 18) states that “Full employment . . . means having always more vacant jobs than unemployed men, not slightly fewer jobs.” Rees (1957, p. 39, chart 5) applies Beveridge’s verbal criterion to the United States. He computes the ratio between number of vacancies and number of unemployed and examines when the ratio crosses 1. Our theory provide a theoretical foundation for Beveridge’s idea that the state of full employment can be assessed by comparing the number of vacant jobs to that of unemployed workers. We find that in the United States, the labor market is at full employment when jobseekers and vacancies are in equal number. Unlike Beveridge, we find that having more vacancies than jobseekers is a sign of inefficient tightness. To borrow language from optimization theory, Beveridge thought that full employment was a boundary solution to the planner’s problem: that the labor market could be either too slack or at full employment. In contrast, we propose that full employment is an interior solution to the planner’s problem: so the labor market can be too slack or too tight, on either side of full employment.

5.2. Early Council of Economic Advisers’ criterion

In the early postwar period, from 1946 to 1956, the Council of Economic Advisers (CEA) used an unemployment rate of 3% as a marker of full employment (Duboff 1977, p. 8).¹⁷ The CEA’s criterion seems appropriate, since the FERU was as low as 3.0% in 1953 and averaged 3.5% for the 1946–1956 period (figure 11). Then the CEA started raising the unemployment rate that it considered as full employment—just at the same time as the FERU was rising (figure 3). In 1962, the CEA announced that an unemployment rate of 4% was “a reasonable and prudent full employment target for stabilization policy” (Duboff 1977, p. 10). Coincidentally, our measure of the FERU is exactly 4.0% at the end of 1961. Just before he became chairman of the Federal Reserve, and after his stint as chairman of the CEA, (Burns 1969, p. 280) reported that “Since the [CEA] identified an unemployment rate of 4 percent with a condition of practically full employment, this figure served as a constant in the equation for computing the potential output.” Again, this is almost the same as the average value of the FERU over 1962–1969, which we measure at 3.9% (figure 3A).¹⁸ Facing rising unemployment in the 1970s, however, the CEA moved away from a numerical target for full employment—maybe to make the departure from full employment less salient. When testifying in Congress in front of the Joint Economic Committee in 1975,

¹⁷In Great Britain, just after World War 2, Beveridge (1960, p. 21) also thought that the FERU was 3%.

¹⁸Interestingly, Burns argues that the number of 4% was not compelling because it does not incorporate information on vacancies. He writes that “we need to develop comprehensive data on job vacancies, so that it will no longer be necessary to guess whether or when a deficiency in aggregate demand exists” (Burns 1969, p. 284). Thirty years after Burns’s article, the government started collecting data on vacancies as part of the JOLTS, which started in 2001. In this paper, we propose a simple method that combines statistics on vacancies with statistics on unemployment to compute the unemployment rate consistent with full employment, and assess in real time departures from full employment.

Greenspan, who was then chairing the CEA, was asked what the target for full employment was; he responded “I do not think we should set a target” (Duboff 1977, p. 13).

5.3. Full Employment and Balanced Growth Act’s criterion

Although it does not define what full employment is, the Full Employment and Balanced Growth Act does give a numerical target for full employment: an unemployment rate of not more than 4% by 1983 (U.S. Congress 1978, p. 1893). This target was quite ambitious. It is lower than the FERU that we compute in 1983, $u^* = 5.0\%$, lower also than the FERU in 1978, $u^* = 5.3\%$, and lower than the average value of the FERU throughout the 1970s, which we estimate at 4.7%. But the number of 4% was in line with the unemployment rate of 4% that was used by the CEA as full-employment target throughout the 1960s, and in fact with the average value of the FERU throughout the 1960s, which we measure at 3.9%. So the numerical target adopted by the Full Employment and Balanced Growth Act was in line with average value of the FERU in the decade before the law was enacted.

5.4. Powell’s criterion

The criterion that the economy is at full employment whenever vacant jobs and unemployed workers are in equal number can be rephrased in terms of labor-market tightness: the economy is at full employment whenever labor-market tightness v/u is one. During the press conference following the May 2022 FOMC meeting, Jerome Powell, the chair of the Federal Reserve, discussed labor-market tightness at length. In response to a question from journalist Howard Schneider asking which tightness the Fed might target, Powell (2022, pp. 12–13) responded: “So in terms of the vacancy-to-unemployment ratio, we don’t have a goal in mind. There’s no specific number that we’re saying, ‘We’ve got to get to that.’ ... I think when we got to one-to-one in the, you know, in the late teens, we thought that was a pretty good number. But, again, we’re not shooting for any particular number.” Our analysis confirms that a vacancy-to-unemployment ratio of 1 is indeed what the Fed should target to satisfy its full-employment mandate—the Fed should be shooting for that particular number.

6. Explaining deviations from full employment

Despite the US government’s full-employment mandate, the US labor market generally deviates from full employment (figure 10). Here we discuss why the US labor market has consistently fallen short of full employment in the past century.

6.1. Great Depression and its aftermath

During the Great Depression and its aftermath, the US economy was exceedingly slack. From the beginning of 1930, when our data begin, to the end of 1941, when the United States enter World War 2, the unemployment gap averages 9.6pp (figure 6). So the US economy was extremely far from full employment. One factor that might have played a role is that the US government and the Federal Reserve did not have a full-employment mandate at the time. The mandate was introduced with the Employment Act of 1946, as a result of the Great Depression. A second factor is that the Federal Reserve was committed to the gold standard, which created a deep deflation in the early 1930s, with dramatic consequences (Eichengreen and Temin 2000). A third factor is that the Fed failed to curb recurrent banking panics in the 1930s (Friedman and Schwartz 1963, chapter 7). Overall, as former Fed chairman Brainard (2021, p. xvii) writes, “Blaming the Depression entirely on the Fed is an exaggeration, but the relatively new and unseasoned central bank did perform poorly.”

6.2. World War 2, Korean War, Vietnam War

Inefficient tightness in wartime. The US labor market was pulled out of its slackness by World War 2. In fact, the labor market became inefficiently tight during the war, with tightness averaging $3.2 > 1$ over the 1942–1945 period (figure 5B). The labor market was once again inefficiently tight during the Korean War, with tightness averaging $1.2 > 1$ over the 1951–1953 period, and during the Vietnam War, with tightness averaging again $1.2 > 1$ over the 1966–1969 period (figure 2B).

Source of tightness. The first question is why tightness was so high in these episodes. Part of the reason is that the government spends a lot during wars, and the amount of spending during these three major wars was extremely large (Ramey and Shapiro 1998). Such expenditure boosts labor demand and then increase tightness (Michaillat 2014). Another part of the reason, is that millions of potential labor-force participants were sent abroad on military duty (U.S. Department of Veteran Affairs 2023). Such drastic reduction in labor force reduces labor supply and leads to elevated labor-market tightness and reduced unemployment rate among the workers who stayed in the United States (Michaillat 2023).¹⁹

¹⁹It might seem obvious that higher labor demand or lower labor supply would raise labor-market tightness. But in standard matching models this does not happen (Michaillat 2014, 2023). The reason is that the labor demand is horizontal in these models. In the matching model proposed by Michaillat (2012), on the other hand, the labor demand is downward sloping so tightness responds to demand and supply shocks.

Absence of tightening by the Fed: World War 2. The second question is why the Fed did not tighten monetary policy to reduce tightness in wartime. Here there is a simple answer. As Brainard (2021, p. xviii) explains, during and shortly after World War 2, “at the Treasury’s request, the Fed held interest rates at low levels to reduce the government’s cost of financing the war.”

Absence of tightening by the Fed: Korean War. The same happened at the beginning of the Korean war, when “facing new hostilities in Korea, President Truman pressed the Fed to keep rates low” (Brainard 2021, p. xviii). The Fed did rebel and was allowed to phase out the low interest-rate peg that had been in place. But such phasing out might have come too late to cool down the Korean-War labor market.

Absence of tightening by the Fed: Vietnam War. The situation during the Vietnam War was different, as described by Brainard (2021, pp. 20–22). The Fed raised interest rates by half a percentage point at the end of 1965, at the exact time when the economy had reached full employment (figure 3B). However, President Johnson was furious that the Fed tightened monetary policy. He needed a low rates to help finance the Vietnam War. Despite the pressure exerted by Johnson, the Fed continued increasing rates in 1966, which rapidly cooled the labor market (as can be seen in figure 3B). Worried about a possible recession, the Fed reversed its previous tightening. The Fed continued swinging between tightening and loosening until 1970, under pressure from the White House and a chaotic political situation. The absence of decisive tightening explains why the labor market was so hot in 1966–1969.

6.3. Postwar period

Inefficient slackness in the postwar period. In the postwar period, the US labor market was generally inefficiently slack (figure 11B)). A manifestation of such pervasive slack is that the unemployment gap averaged 1.6pp over the 1946–2019 period. Another manifestation is that the labor market was not at full employment once from 1970Q1 to 2018Q1: it was inefficiently slack during that time, almost half a century!

Elevated target. A first possible reason to explain this slackness is that the only measure of full employment readily available to the Fed and policymakers is the NRU computed by the CBO. Over 1949–2019, the NRU averages 5.5% (U.S. Congressional Budget Office 2024). This is 1.4pp above the average of the FERU over the same period, which is 4.1%. So policymakers might have targeted an unemployment rate that was just too high. The average distance between the FERU and the NRU almost explains by itself the entire average postwar unemployment gap.

Priority to inflation. A second reason that might explain the slackness of the US labor market in the postwar period, especially after 1970, is that the Fed prioritized inflation at the expense of unemployment. Thornton (2011) reviews policy directives by the Federal Open Market Committee (FOMC) and finds that it made no reference to unemployment or full employment in its policy directives between 1979 and 2008—despite the dual mandate introduced by the 1977 and 1978 acts. Instead, Thornton finds that the FOMC preferred “to state its objectives in terms of price stability and economic growth.” This changed at the end of 2008, when the FOMC started mentioning its dual objective of “maximum employment and price stability” in its policy directives and policy statements. This focus on inflation is confirmed by Kaya et al. (2019) using FOMC transcripts from 1960 to 2010. They find that the FOMC discussions have increasingly emphasized inflation relative to unemployment and that this shift occurred during the Volcker era and continued even as inflation itself declined. They conclude that “the emphasis on inflation has become entrenched and disconnected from actual inflation.”

Possible reasons behind the prioritization of inflation. This focus on inflation might be due in part to a change in the central banker’s preferences change or in macroeconomic theory. But in part it also appears to come from pressure from Congress. Hess and Shelton (2016) examine legislative activity to determine when Congress threatens the Fed and whether this pressure affects monetary policy. They find that by the late-1980s Congress shifted from threatening the Fed when unemployment was high to threatening when inflation was high. This finding is consistent with Weir (1987, p. 377)’s view that “By the mid-1980s full employment had been all but erased as a major political issue in the United States.” In fact, Weir (1987, p. 395) argues that although the CEA under President Kennedy identified an unemployment rate of 4% as full employment, in the following decades “more conservative economists [offered] ever-increasing rates of unemployment as the ‘true’ definition of full employment.”

6.4. Great Recession

Zero lower bound. The Great Recession saw the highest unemployment gap of the 1946–2019 period, and it presented new challenges to the Fed. Although the unemployment rate and unemployment gap skyrocketed in 2008–2009, the Fed was unable to respond because it ran against the zero lower bound on nominal interest rates at the end of 2008 (Board of Governors of the Federal Reserve System 2024). Even if the Fed had wanted to reduce the unemployment rate further, it could not because it was constrained by the zero lower bound until 2015. As a result the unemployment rate remained inefficiently high until the end of 2018 (figure 3B).

Elevated target. The Fed did resort to unconventional monetary policy, such as forward guidance and quantitative easing, to reduce long-term interest rates (Kuttner 2018). But the effectiveness of such policies remains debated (Greenlaw et al. 2018). Moreover, they might not have used these policies as aggressively as they should have because once again the unemployment rate that they targeted was much too high. The Fed commonly uses the CBO's NRU as indicator of full employment. During the Great Recession the CBO opted to adjust their natural rate upward by 0.9pp to capture structural factors that according to them, in the short-term, kept the unemployment rate high. As a result, in 2011Q4, the NRU reached 5.8% (U.S. Congressional Budget Office 2021). We do find that the outward shift of the Beveridge curve lead to an increase in the FERU after the Great Recession by 0.5pp, but the FERU stood only at 4.5% in 2011Q4, so 1.3pp below the CBO's NRU (figure 3A).

6.5. Coronavirus pandemic

Zero lower bound. The coronavirus pandemic lead to a sharp slowdown in economic activity. In 2020, the US economy reached the largest unemployment gap since the Great Depression, at +6.4pp (figure 8B). As during the Great Recession, the Fed was unable to respond more aggressively to the slackness of the economy because it rapidly hit the zero lower bound (Board of Governors of the Federal Reserve System 2024).

Recovery. The US economy recovered fairly rapidly from the pandemic, however, thanks to aggressive expansionary fiscal policy (Romer 2021). The US economy reached full employment in 2021Q2, and continued tightening after that. In 2022Q2, labor-market tightness reached 2.0, a level it had not seen since the end of World War 2 (figure 10B). It is only then, in spring 2022, that the Fed started tightening monetary policy (Board of Governors of the Federal Reserve System 2024). It is unclear why the Fed start tightening monetary policy earlier. One entire year passed between the labor market becoming too tight (spring 2021) and the Fed increasing rates (spring 2022). This delay is especially surprising since inflation was also above its target of 2% at the time: core inflation was 3.7% in 2021Q2 and rose to 6.3% in 2022Q1 (U.S. Bureau of Labor Statistics 2024b). This delay in tightening monetary policy, combined with the one-to-two years it takes for monetary policy to take full effect (Coibion 2012), explains why the labor market has been inefficiently tight until the end of 2023.

7. Conclusion

To conclude, we discuss possible uses of the FERU formula for the conduct of monetary policy.

Full-employment target. In the United States, the Federal Reserve is mandated to stabilize the economy at full employment. However, there is no agreed-upon standard of what is the unemployment rate at full employment, which makes it difficult for the Fed to design policy to achieve full employment, and makes it difficult to assess the performance of the Fed in satisfying its full-employment mandate (Duboff 1977, p. 3). In this paper, we argue that the legal notion of full employment should be translated into the economic concept of labor-market efficiency, and accordingly, that the unemployment rate $u^* = \sqrt{uv}$ is the appropriate measure of full employment. The Fed could use it as their full-employment target—especially since \sqrt{uv} can be measured in real time.

Optimality of the full-employment mandate. This paper argues that the legal notion of full employment and the economic notion of labor-market efficiency are one and the same. This is a convenient property: since the social planner and the US government have the same objectives, insights from optimal policy analysis have direct practical implications. In particular, maintaining the economy at full employment is the optimal policy in a range of monetary models with a Beveridge curve in which the Fed, by choosing the interest rate, can control aggregate demand and thus the unemployment rate.

Optimal monetary policy with fixed inflation. For instance, the model by Michaillat and Saez (2022) has a horizontal Phillips curve, so inflation is fixed and the Fed does not need to worry about its price-stability mandate. Then the optimal monetary policy keeps the economy at full employment, so the unemployment rate should always be at $u^* = \sqrt{uv}$.

Optimal monetary policy with divine coincidence. The model by (Michaillat and Saez 2024) have not a horizontal but a downward-sloping Phillips curve: higher unemployment leads to lower inflation. Furthermore, the Phillips curve goes through the point of divine coincidence: when the unemployment rate is efficient, inflation is on target. Therefore there is no trade-off between inflation and unemployment: maintaining the unemployment rate at its efficient level also guarantees that inflation is on target. Therefore the optimal monetary policy is once again to maintain the unemployment rate at $u^* = \sqrt{uv}$.

Optimal monetary policy without divine coincidence. In models in which the divine coincidence fails, monetary policy faces a tradeoff between closing the unemployment gap and bringing inflation to its target. It is no longer optimal to eliminate the unemployment gap and simply target the FERU. Nevertheless, the unemployment gap remains useful to design policy, but it has to be weighted against the inflation gap to determine what the optimal monetary policy is.²⁰

²⁰The same is true in the case of optimal fiscal policy. It is not optimal to use government spending to close the unemployment gap because government spending does not perfectly substitute for private spending.
